Paper presented at the Annual Conference of the  
Population Association of America,  
Los Angeles, March 30-April 1, 2006

## **Childlessness and educational attainment among Swedish women born in 1955-59**

by Jan M. Hoem, Gerda Neyer, and Gunnar Andersson

### **Abstract**

In this paper we extend the concept of educational attainment to cover the field of education taken in addition to the conventional level of education attained. Our empirical investigation uses register records containing childbearing and educational histories of an entire cohort of women born in Sweden (about a quarter-million individuals). This allows us to operate with a high number of educational field-and-level combinations (some sixty in all). It turns out that the field of education serves as an indicator of a woman's potential reproductive behavior better than the mere level attained. We discover that in each field permanent childlessness increases some with the educational level, but that the field itself is the more important. In general, we find that women educated for jobs in teaching and health care are in a class of their own, with much lower permanent childlessness at each educational level than in any other major grouping. Women educated in arts and humanities or for religious occupations have unusually high fractions permanently childless.

Our results cast doubt on the assumption that higher education per se must result in higher childlessness. In our opinion, several factors intrinsic and extrinsic to an educational system (such as its flexibility, its gender structure, and the manner in which education is hooked up to the labor market) may influence the relationship between education and childlessness, and we would not expect a simple, unidirectional relationship.

## 1. Introduction

This paper is about the association between educational attainment and permanent childlessness among women. There is a lot of interest in this issue in the academic literature and lately also in the public debate. One of the most common perceptions about the effect of educational attainment on childbearing is that more education leads to lower fertility. Manifold explanations have been given for such an observation. Economists argue that higher education results in higher opportunity costs of childbearing for mothers (because they get lower rewards for their investment into education) and in higher direct costs of children (because more highly educated parents invest more than others in each child); this should lead to lower fertility (Becker 1960, 1981; Cigno 1991). It is further argued that higher education reduces a woman's economic dependence on a (male) earner (Oppenheimer 1994). This would increase the share of non-married women among the highly educated at each stage in life, which in turn would lead to a higher observed rate of childlessness among highly educated women when marital status is disregarded in the empirical analysis (Grünheid 2004; Blossfeld and Jaenichen 1992a; Blossfeld and Huinink 1991; Kiernan 1989; Hobcraft and Kiernan 1995).

Scientists focusing on cultural issues often interpret fertility differentials among women at different educational levels as a consequence of the greater range of possible lifestyles and other choices increasingly available to women as their educational attainment improves (Lesthaeghe 1983; van de Kaa 1987; 1996; Surkyn and Lesthaeghe 2004; Lappegård 2002). The wish for children is assumed to lose out in this greater range of options. In a similar vein it is argued that women lower their preferences for children as they proceed with their education (Rindfuss, Morgan, and Offutt 1996). Finally, a higher rate of childlessness among more highly educated women is in part attributed to their longer stay in education. Empirical studies regularly find that childbearing rates are lower during periods of enrolment in education, irrespective of which level of education a woman has attained already. Prolonged education may therefore lead to a postponement of childbearing up to an age when biological factors may make it more difficult to conceive (Rindfuss and Bumpass 1976; Rindfuss, Bumpass, and St. John 1980; Kravdal 2001; Gustafsson 2001).

On the whole, most researchers who study the association between educational attainment and fertility focus on two dimensions of education: First, they concentrate solely on the level of education and its impact on fertility. Second, they perceive educational attainment primarily as an individual attribute and use it as a proxy for a person's human, economic, cultural, and to some extent biological capital. We add two new dimensions to this picture, namely (i) the field of education and (ii) institutional aspects of the educational system. We show that the field of education is an essential determinant of ultimate childlessness. To make sense of this finding we propose that explanations of the relationship between education and fertility should consider the institutional context within which women and men decide which education to take and the context in which they are educated. Aspects of the educational (and occupational) system play a central role in shaping final fertility outcome. One may get a distorted impression of the relationship between education and fertility if either of these two extra dimensions is left out of account.

In Section 2 we spell out our reasons why we feel that the field of education is important and why institutional aspects might influence childbearing behavior. We concentrate on (i) the structure and flexibility of an educational system, (ii) the relationship between the educational system and the labor market, and (iii) the impact of preferences and social norms. With our application to Sweden in mind we devote Section 3 to a description of the main features of the Swedish educational system.

Section 4 contains the main results of our investigation, namely the empirical relationship between the field of education and permanent childlessness in Sweden. Like most others, we find lower fertility (in the present paper manifested as higher permanent childlessness) to be associated with more education for women in each educational field. It turns out, however, that the field of education is at least as important as the level attained, and that one cannot generally maintain the assumption that higher education leads to lower fertility.

In a companion paper (Hoem, Neyer, Andersson 2006) we will extend this exploration by a study of the connection between a woman's field of education and her ultimate number of children. We split the material in this manner because it is too extensive for a single paper.

Both papers use the same data set, namely register records containing individual-level childbearing and educational histories of women born in Sweden since 1945. We have concentrated our presentation in both papers on the cohort of women born in 1955-59. We have chosen this single five-year birth cohort in part because we have wanted to focus on women who largely had reached the end of their reproductive period at the time of data extraction, but also for reasons of data quality. Younger cohorts have not become old enough and older cohorts have worse data (see Appendix 1).<sup>1</sup> Extensive cleaning and reorganization of the original register data has been needed, but the details of that process are not essential for an understanding of our findings. An account of the data quality and data cleaning along with some reflections on our (very simple) method of analysis can also be found in Appendix 1.

It is legitimate to ask whether the character of our results can be replicated in other settings. In an investigation on first-birth risks of Norwegian women Lappegård (2001, 2002) and Lappegård/Rønsen (2005) found patterns in such dynamics that resemble what we present here. Our Norwegian colleagues use broader categories of fields of education than we do in this paper, and they differentiate by field of education only for women with higher education. In our present study we employ more refined categories of fields of education and we investigate to what extent different levels of childlessness can be found also among women who do not hold a university degree. This approach leads us to expand the theoretical assumptions about the relationship between fertility and education. It remains to be seen to what degree findings of this nature can be extended to other types of countries.<sup>2</sup>

## **2. Why fertility research should pay attention to institutional aspects and to the woman's field of education**

To focus on the level of education alone means that one only pays attention to a single dimension of an educational system, namely its vertical differentiation. It is important to also take into account its horizontal differentiation, viz., the field, line or

---

<sup>1</sup> We get largely the same results when we check the less complete data for the neighboring five-year cohorts, but we do not report any details about them here.

<sup>2</sup> Studies that consider the field of education and its relationship to childbearing are rare, and they mostly focus on selected educational groups (Vessillier 1976; 1989; Jensen 1973; Cookingham 1984; Bressler and Kephart 1954; Cooney and Uhlenberg 1989; Preston 1994).

type<sup>3</sup> of education, and we present the reasons why in this section. Our argument emphasizes a number of aspects. The choice of educational field surely reflects a person's preferences, which may include her attitude to childbearing. The educational line is also part of what determines a person's environment during her formative years. Furthermore, the choice of educational orientation has a decisive impact on a person's future employment, so we need to consider the ways in which education and the labor market are connected. It also determines other parts of her future social environment and its norms. All these aspects are important for childbearing behavior. Let us now address the most important of these issues.

2.1. Childbearing and the educational system. The structure of the educational system is of course decisive for a person's educational career, for the level of education that a person attains, and for the field in which she takes her education. Several aspects of the structure potentially have an impact on fertility, but to our knowledge they have so far not been considered in demographic research. One may speculate whether, for example, educational systems with an integrated scheme of vocational training have different consequences for childbearing behavior than "dual" educational systems where vocational training is provided through apprenticeships in firms, given, for example, that these two systems involve different environments during instruction and different timings of entry into the labor market. Similarly, one may generate hypotheses about childbearing consequences of educational systems that require early decisions about the educational career vs. educational systems that do not separate pupils at an equally early stage in life. We believe that two endogenous features are particularly relevant, namely (1) the system's flexibility and (2) the gendered pattern of educational fields. Here is why we think that these two aspects are important for fertility research.

*2.1.1. The flexibility of the educational system.* Educational systems vary in their flexibility. Some educational systems (e.g.: those of the Nordic countries) avoid early track differentiation and remain highly permeable. They allow pupils and students to change their educational tracks, to alter their main field of education (within wide bounds) at all levels, and even more importantly to exit from post-compulsory education and to re-enter it at all stages in their lives. Other educational

---

<sup>3</sup> We use the terms "field", "type", and "line" of education as synonymous with each other and with "educational orientation" in our papers.

systems are more rigid and have limited opportunities for pupils and students to modify their educational decisions, to alter their field of education, or to resume education after interruption. Such differences in system flexibility must have an impact on fertility. Flexible educational systems offer a person better opportunities to adjust her education to the development of her interests and talents, to changes in the life-course (Henz 2001), and to changes in her plans for her future life. If a woman initially chooses a field of education that turns out to lead to an occupation that is less conducive to childrearing than she expected, she can re-enter the educational system and take a new education in a field that she sees as better compatible with her childrearing plans.<sup>4</sup> A flexible educational system should therefore make it easier for a woman to have children because she does not need to see childbearing as having an irrevocable impact on all other aspects of her life course.

2.1.2. *The gendered structure of the educational system.* Most educational systems are sex-segregated. Over recent decades, the gender differences in the level of educational attainment have diminished as the share of women participating in education beyond the primary level has increased in most countries. In much of the West, women now constitute the majority among entrants, participants, and graduates at the secondary level and in some fields even at the tertiary level (Jönsson 1999; OECD 1998, 92; OECD 2001, 41; Müller and Wolbers 2003).

The restructuring of gender patterns in fields of education has not matched the development in the levels of education, however. In fact, the gender division in the types of education has remained remarkably persistent (Bradley 2000). Even in Sweden, which has made special efforts to reduce such gender gaps, women and men have largely continued to choose different fields of education. Girls and women usually crowd into educations for care, nursing, and other health occupations, and into teaching, arts, humanities, and personal services, while as before boys and men crowd into educations for crafts, trade, industry, engineering, and the natural sciences (OECD 2001, 173; Melkas and Anker 1998; Smyth 2003, 61f.; Charles and Bradley 2002). In these fields, the gendered pattern of female- vs. male-dominated lines occurs on all

---

<sup>4</sup> Of course, the reverse is also possible. A woman who chooses a field of education mostly because she assumes that it will lead to an occupation where childrearing and employment are compatible, might later change her mind and move to a field that she likes better, even if it may be less conducive to childbearing.

educational levels; in other fields, for example business and administration, the gender distribution changes as one progresses from one level to the next.<sup>5</sup>

The growing tendency among women to take higher education has altered their childbearing behavior. Most notably, the greater participation in education has contributed much to the increase in the age at first birth seen in most countries. We know less about the effect on childbearing behavior of the narrowing gender gap at each educational level on the one hand and the persistence of gender segregation across educational fields on the other. An increase in the share of women in education alters girls' and women's social environment during the time they are in education. They stop being "token" women or a "skewed" group (Kanter 1977a; 1977b) and no longer constitute a minority so small that their socialization in school is primarily determined by the norms, attitudes, and behavior of men (Kanter 1977b). They have greater opportunities of socializing with other girls and women at the same educational level in the same educational field, including communicating about reproduction (Watkins 1995). They have better options of "doing gender" and they thus have a broader spectrum available for developing their own identity, including their identity as women and potential mothers (West and Zimmerman 1987; West and Fenstermaker 1995; Gildemeister/Wetterer 1992; Dausien 1999). Contrary to a purely economic point of view, which ties fertility to opportunity costs only, one would therefore expect that childlessness among highly educated women would decrease as the share of women with higher educational attainment or in specific educational fields increases.

By a similar argument, studying in female-dominated lines may provide an educational environment that encourages subsequent childbearing. Some female-dominated lines (such as home economics) are even often regarded as conveying more stereotyped images than others of womanhood and motherhood. The lines that have such a stereotyping function may vary from country to country and may change over time, but they are assumed to reinforce women's self-perception as mothers and carers. Even when they do not transmit stereotyped images of womanhood, female-dominated educational lines are nowadays often seen as providing a more supportive

---

<sup>5</sup> According to a recent study, education at the upper-secondary level in the social sciences and in business is female-dominated (more than 60% female) in all European countries, while at the tertiary level the female dominance vanishes (between 40% and 60% female; Smyth 2003, 63).

environment for women than male-dominated fields of education.<sup>6</sup> Being educated in a female-dominated field may therefore support a life-course orientation that comprises both a professional career and having children. This should work toward lower childlessness among women who have got their education in a female-dominated area than among other women at the same educational level.

2.2. Education and the labor market. We now turn to aspects that may affect the relationship between educational attainment and childbearing behavior through the link between education and the labor market. The main lines of that link are that a woman's field of education will have a decisive impact on her future labor-market options, on how easy it becomes to "use" her education in the labor market, on her work-place environment, on the stability and protection of her employment, and on her income perspectives. (See contributions in Müller and Gangl 2003). All of these features have important bearings on her childbearing behavior. For the sake of a systematic approach, we briefly outline four aspects that are relevant for our topic.

*2.2.1. Job security.* Different types of education lead to occupations with different employment security. In particular, some educations lead to jobs in the public sector more readily than others. Examples are educations for teaching, nursing, welfare, and police work, and in some countries also education in law or the medical or pharmaceutical professions. In Scandinavia, and also in many other countries, the public sector offers much better job security than the private sector does. In many countries, the public sector has also pioneered work arrangements that facilitate the compatibility of motherhood and employment, such as granting parental leave and part-time work with a guarantee of job continuation and return to full-time work after the end of the early childrearing period, or such as offering additional income compensations to a parent on parental leave. We therefore expect women with an education that leads to employment in the public sector to display lower childlessness than women with an education that leads to predominantly private-sector employment. In other words, women with an education as nurses should have lower childlessness than women with educations for textile work, the hotel- and restaurant business, or busi-

---

<sup>6</sup> For a review of the literature see Jacobs 1996. He reports on studies that compare women-only colleges to co-educational ones, but the findings should also apply to female-dominated fields of education in general.

ness and private administration; likewise women trained to be high-school teachers should have lower childlessness than women educated in journalism.

*2.2.2. Job content and job prospects.* Fields of education vary concerning the prospect of finding a job one is trained for. Some educational lines may have a considerable mismatch with available occupations, and for some there may in fact be no obvious set of occupations that the education leads to. Typical examples are general educational degrees or certificates, for instance in fine arts, humanities, or general language skills. Persons with such a background must often go through a prolonged job search and may end up with a lower occupational status than they expected, fewer occupational rewards, lower income, or a higher risk of unemployment (Allmendinger 1989; Wolbers 2003; Konietzka 2002; Gangl 2003a; 2003b). In such a situation motherhood may be postponed and permanent childlessness may be more likely.

*2.2.3. Skill depreciation.* The problem of skill depreciation during periods of absence from the job is much more acute for some educations than for others. In general, technological skills tend to depreciate more quickly than skills in the service sector.<sup>7</sup> Because they risk that their skills become outdated if they take a job break, women with an education with a high “atrophy rate” may have more childlessness than women with an education that does not depreciate as rapidly in case of employment interruption or reduced employment.<sup>8</sup>

*2.2.4. Gender dominance on the job.* Some educations prepare for an occupation in labor-market segments with a high share of female employees, while some others train for jobs in male-dominated occupational sectors. The latter include such areas as technology, mechanical engineering, or some natural sciences; while teaching, nursing, or personal services are usually highly feminized occupations (Smyth

---

<sup>7</sup> In such matters, the structure of the educational system may be important, as is whether it provides firm-specific education or more general, occupation-specific education (Estevez-Abe et al., 2001). There is also some variation over time. For example, technological advancement in an area like information technology has made specific qualifications such as secretarial skills change so tremendously during the past two decades that their „atrophy rate“ must have increased considerably.

<sup>8</sup> Depreciation effects may be counterbalanced by educational policies that offer recurrent education or retraining after employment interruption, something that again highlights the role of educational-system flexibility. Skill depreciation may further be mitigated through family policies that discourage long employment interruptions and support job retention during early childrearing years (see Hoem, Neyer, Andersson 2006).

2005).<sup>9</sup> One normally assumes that employment areas with a high share of female employees provide an environment in which pregnancy and motherhood are quite common and which is therefore conducive to childbearing.<sup>10</sup> Female-dominated sectors often offer high job flexibility, more part-time opportunity, and more exit and (re-)entry options. One would also assume that they hold greater promise that employers are accustomed to the needs of childrearing parents and that employment and childcare are more compatible than elsewhere. However, female-dominated areas are also areas with a low income profile, “de-regulated” working hours, non-standard, non-insured, time-limited, or other precarious work arrangements, gender-segregated career tracks, less skill and employment protection, fewer upward career possibilities, and sometimes even less compatibility with childrearing (Anker 2001; England 1982; 1984; Budig and England 2001; Hultin 2003). By contrast, male-dominated occupations typically pay comparatively higher wages, also for women, but may have time-demanding work norms or a male-dominated work environment, such as standard or longer working time, less consideration for employees’ needs to give care, and often a working culture dominated by “masculinity”. All in all, childlessness may be lower among women with an education that leads to female-dominated occupations than among women with an education that leads to male-dominated occupations. However, even some female-dominated fields may have work conditions that make more women refrain from having children, which would lead to higher childlessness in such female-dominated areas.

### 2.3. Selection and adaptation, preferences and social norms

Some researchers argue that institutions such as the educational system, the gender system, and the occupational or “skill system” mainly constitute the framework within which women make their decisions regarding their education and childbearing. For instance, preference theorists maintain that a woman’s choices may be influenced by her social and family background, but that it nevertheless is her personal decision which field of education and which family form she chooses among the options available to her; institutions are only secondary in shaping education and family-life decisions. As a consequence the impact of institutions on education and family-life choices should vary between different preference groups (Hakim 1998,

---

<sup>9</sup> The degree of feminization may vary over time and across educational levels.

<sup>10</sup> See also our corresponding argument in Section 2.1.2.

2003). This view corresponds to the demographers' age-old concept of self-selection (Goldman 2001). In essence, preference theories and "self-selection approaches" assume that the personal traits and interests that make some women more prone to choose a specific educational line may also be associated with their proneness to have children. For example, women who are interested in social relationships and in other people should be more likely to opt for an education in which they can work closely with people, such as educations for teaching, health care, social work, anthropology, and so on. At the same time they may be more inclined to have children than women who are less interested in personal relationships and in other people.

Preference theories (and corresponding selection approaches) are often formulated as if they assume constancy of preferences over the life course.<sup>11</sup> Their arguments usually assume that women select themselves into different educational and childbearing tracks early in life and that their attitudes and plans change very little. To us it seems at least as plausible that preferences are shaped dynamically by social environments and influenced continuously by social norms (that may evolve in their own right). Elster regards social norms as "emotional and behavioral propensities of individuals" that are "shared with others and maintained through interactions with others" (Elster 1991, 113f., *our italics*). This would imply that there exist specific norms for specific social groups or cohorts in society, norms that are formed and maintained and re-enforced through interaction with people who belong to the same social group. As for the relationship between educational line and childlessness, we would assume that different educational lines lead to labor-force and occupational situations with different social norms regarding work behavior, social behavior, and also regarding family and childbearing behavior. As life goes on, women would adapt their childbearing preferences and behavior to their social environment. Factual constraints and opportunities, such as employment opportunity, work conditions, work demands, or income, represent one set of factors that bring about adaptation of childbearing intentions; social norms attached to educational and occupational groups represent a different set of such determinants.

---

<sup>11</sup> This is an essential ingredient in Beckerian economics.

## 2.4. Summary

We conclude that several factors intrinsic to educational systems, to the link between education and the labor market, and between education, preferences, and social norms make us doubt any assumption that the educational level alone may be sufficient to explain the relationship between education and childlessness. In particular, we doubt that higher education per se must result in higher childlessness. Our analysis needs to include items that pick up institutional aspects of the educational system, such as its organization (e.g. its flexibility) and its structure (in particular its gender structure). Such items should reflect the role of institutional arrangements as determinants and should also serve as markers of individual preferences or social norms. At the current stage, these two types of roles cannot be disentangled with available data, and for our purposes that is not necessary either. For the time being we see a combination of the level and the field of education as a sufficient step forward toward better insight.

## **3. The Swedish educational system**

It follows from our reasoning above that the structure and organization of an educational system may have a decisive influence on fertility outcomes. In this section we briefly sketch the main elements of the Swedish educational system, highlighting factors that are relevant for our analysis. Henz and Jonsson (2003) pick up many of the same threads as us in their concise description of the Swedish system.

In addition to promoting educational attainment, the Swedish educational system aims at furthering social equitability, at encouraging recurrent education, and at aligning education to the changing needs of society and labor markets (Elgqvist-Saltzman 1988; Rusak 1977; Meghir and Palme 1999; Marklund 1981; Bron-Wojciechowska 1995). To this end it has been set up as a uniform and flexible educational system with basically three levels of education, as follows.<sup>12</sup>

---

<sup>12</sup> The basis for this system was laid in the 1960s and 1970s. The cohort on which our empirical analysis focuses, namely women born in 1955-59, were among the first to be educated under this system. We indicate the main features of the system during the period when most members of our cohort attained their highest educational level.

Primary education consists of a nine-year comprehensive and co-educational school, mandatory for all children between 7 and 16 years of age. The curriculum is largely the same for all pupils at this level.

Upper-secondary education<sup>13</sup> is mostly directed toward pupils aged from 16 to 18 or 19 years, though Sweden has an extensive system to provide such education to individuals who “missed out” as teenagers. It is an integrated system covering both vocational and theoretical education. The curriculum is set up in a way intended to allow pupils to adapt their training according to their abilities and interests (Erikson and Jonsson 1996; Breen and Jonsson 2000). During the 1970s and 1980s, the period most relevant for our cohort, upper-secondary school encompassed both two-year and three-year lines. The two-year lines (which were turned into three-year lines in the 1990s) mostly accommodated vocational or semi-vocational lines of education, such as education to become an office-worker, textile worker, mechanic, electrician, or health-care worker. The three-year lines comprise academic study programs such as general education in the humanities, business, or natural sciences. All three-year lines grant direct access to tertiary (“higher”) education. Various extensions to and specializations following a two-year program can also produce a secondary education normed to be of three years’ length. Almost all pupils continue to upper-secondary school after compulsory education (Marklund 1981, 203; Marklund and Bergendahl 1979, 13; Henz and Jonsson 2003, 238).

Higher education is given at three levels. (i) “Lower-tertiary” education is scheduled to last for two to three years and has a focus on advanced vocational training. Educations to become a nurse, midwife, music and arts teacher, youth worker, or laboratory assistant, to name a few, are all provided at the lower-tertiary level. (ii) “Upper-tertiary” education is scheduled to last at least three to four years and corresponds to an American undergraduate college education, going up through the B.A./B.Sc. and the M.A./M.Sc. in the Swedish case.<sup>14</sup> Upper-tertiary education is required for, say, high-school teachers, psychologists, social workers, physicians, or lawyers. (iii) Advanced studies beyond this level lead to research degrees (Swedish licentiate and doctoral degrees), corresponding in principle to an American Ph.D. or to a continental-European research doctorate.

---

<sup>13</sup> Since lower-secondary school is integrated into the compulsory primary education, the upper-secondary education is sometimes simply called secondary school.

<sup>14</sup> The Swedish titles are different.

Higher education has also been open to students who have not acquired access through secondary education, in particular to adults with work experience (Marklund 1981, 204; Elgqvist-Salzman 1988, 494). Women and men of age 25 or more with at least four years of gainful employment have been eligible to apply to enter higher education even if they had not completed a form of secondary education that would otherwise have granted them direct access to higher education (Marklund 1980, 271).

Continued education and social equality in educational advancement are supported through an extensive system of adult education and through a system of financial assistance for people in education. Education for adults is offered at all levels of instruction and in various forms, for example as labor-market training, in-service training, supplementary education, or continuing education to enhance schooling in general.<sup>15</sup> Employees have the right to take a break in employment in order to receive instruction, with a guarantee of a return to employment after the completion of education.

All students in higher education are entitled to financial assistance.<sup>16</sup> This benefit consists in part of a grant that is not paid back, and for the main part of a loan that is repaid over 25 years or by the time when the borrower reaches age 60 (The Swedish Institute 2004; Salerno 2002, 40). During educational enrollment, employees who have interrupted their employment to continue their studies have received governmental subsidies corresponding to a high fraction of a regular salary (Marklund 1980, 205). Several other financial benefits are available for unemployed persons under re-training and for adults who want to complete upper-secondary education. The entitlement to financial study assistance is an individual right. This means that neither the parents' nor the partner's economic circumstances are taken into account when an application is considered.<sup>17</sup>

The focus on continued education and on (re-)education geared to the needs of the labor-market has two consequences. First, the share of people with no more than primary education is rather low in Sweden (Müller and Wolbers 2003). In our cohort (women born between 1955 and 1959) 18% have primary education as their highest

---

<sup>15</sup> See Swedish National Agency for Education (2004) at:  
<http://www.skolverket.se/english/system/index.html>

<sup>16</sup> The assistance is granted up to age 51, but has reduced amounts for those aged 41 and above (The Swedish Institute 2004).

<sup>17</sup> The student's own income is taken into account, however, and for very high individual incomes the amount of financial assistance is reduced (The Swedish Institute 2004).

educational attainment.<sup>18</sup> Slightly over half of all women has completed upper-secondary school (37% on a two-year line and 15.5% in a three-year education), and almost one third (29.5%) has a higher educational degree.

Second, the educational system provides a high degree of flexibility. An early choice of educational direction does not rule out other educational possibilities later in life. The opportunities for recurrent education allow individuals to resume their education, to upgrade it, to complement it through additional study, or to change their field of education at any stage in their lives, according to their interests, abilities, motivation, work, or family needs. Although it does not happen very often, a person with a degree at a higher educational level may in principle return to take education at a lower educational level. For example, a person who has a university degree in the humanities at the “upper-tertiary” level may retrain as a youth worker, which is a “lower-tertiary” education. Education is also not segregated from adult working life. People taking upper-secondary or tertiary education commonly interrupt their studies for a while to work in a job and to resume their studies later (Marklund 1981, 203). A large share of the students in higher education have working experience and are over 25 years old (Marklund 1981, 204). Contrary to what may be the case in many other countries, alternating education and employment or combining part-time work with part-time education is actually the most common path through education in Sweden (*ibid.*; Breen and Jonsson 2000; Erikson and Jonsson 1996).

As a consequence of the flexibility of the Swedish educational system, many women continue their education during the period of childrearing. When educational enrollment extends well into a woman’s fertile years and she starts to have children, it of course has considerable consequences for her educational progress, even in the most helpful of systems. Therefore, we like to see childbearing and education as dynamically interactive processes that individuals do their best to control as they go along. It is too simplistic to believe that the choice of an education is directed by clear goals which individuals set for themselves at an early age and which they subsequently pursue in a linear and cumulative manner until education is completed, after which jobs are sought and union formation as well as childbearing follows. Swedes do not always build up their educational attainment in such a monotonic manner, adding exam to exam without ever retracing their steps or changing their minds about how

---

<sup>18</sup> The share is calculated excluding the 4.8% of women whose education is not recorded in the data.

they want their education to be. Nor do they just leave the educational system upon completion of an education and get themselves a job and then children, never to return to take more education. Throughout the young-adult years and beyond, there is movement into and out of education. (In our companion paper we shall show how this is picked up in our data.) In this process, a woman's perceptions will be honed against the realities of educational and occupational life, and there will be a process of adaptation of the individual to life's possibilities.

Thus, "unordered" educational careers, such as interruption of education, changes in the field of studies, and resumption of studies in the same or a different field, have become a common feature of the pursuit of education in Sweden (Breen and Jonsson 2000, 758). Viewing education, work, and childbearing together, we find that what Rindfuss et al. (1987) and Jonsson (2001) have called "disorder of the life-course" is the order of the day in Sweden.

The aim to achieve equality in educational opportunity in Sweden has led to a decline in the effect of gender on overall educational attainment (Shavit and Blossfeld 1996, 238f.). The differences between men and women in educational attainment have decreased, and for some educational levels even reversed (Elgqvist-Saltzmann 1988, 495; Stanfors 2003, 74; 153). Nevertheless, women tend to choose shorter educational lines than men do, so that a gender gap remains at more advanced educational levels.

Despite the increase in the share of women in secondary and tertiary education, gender segregation by field of education persists (Stanfors 2003, 78, Table 4.3). Women constitute the vast majority of upper-secondary graduates in personal care, health care, arts, social sciences, and business and administration, but only a minority in science and technology (Stanfors 2003, 254, Table A8.18). At the tertiary level, women largely outnumber men in the areas of health, teaching, arts, and humanities, but they are less well represented in technology and the natural sciences (Elgqvist-Saltzmann 1988, 496). The gender gap seems to be less pronounced in such areas as law and social sciences. However, within these broad fields of study, the gender distribution varies greatly. In the social sciences, for example, women crowd into areas like social work while they make up "only" about half of the graduates in law. In teaching, women dominate the study lines of primary-school teaching, education for children with special needs, or child- and youth pedagogics, but they do not outnumber men in education for upper-secondary teaching. In the technical and natural sciences, women choose study lines like druggist, pharmacist, or veterinarian,

or study to become professionals in the natural sciences, and they opt less often for civil engineering or for engineering in general (Elgqvist-Saltzman 1988, 496; Statistics Sweden 1997, 375ff.). On the whole, programs designed to break gender-stereotyping in educational choice have worked asymmetrically; girls and women have entered science and technology to a greater extent than boys and men have taken to female-dominated educations (Stanfors 2003). Therefore, if we look at broad subject categories, girls and women (in secondary and tertiary educations) have come to display a wider spectrum of subject choices than boys and men do, but the gender pattern of educational fields nevertheless remains pronounced.

#### **4. Main results**

4.1. Main features. Figure 1 contains our main results on permanent childlessness among women in our selected cohort, namely the one born in Sweden in 1955-59. The diagram is based on the information in Table A2 (see Appendix 2). We operate with close to sixty educational groups in that table, and have written the name of a selection of them into the diagram. We have indicated the various fields of education by markers of various forms and colors.

[Figure 1 about here]

Like most others, we find lower fertility (in this case higher permanent childlessness) to be associated with more education for women, but in our data this only holds in each educational field. The trend-lines included in the diagram for selected educational fields and over the various educational levels illustrate this. An equally important feature of the diagram is, however, that the educational orientation is at least as important as the level attained. For instance, and to start of with some contrasting examples, women who have completed no more than primary school or lower secondary school have a similar level of childlessness (14.7%) as teachers of children with special needs (14.1%), home-economics teachers (14.3%) or physicians (15.9%) do, all of which have a higher tertiary education. The same holds for women who have an education as cleaners (15.5%), mail carriers (14.7%), typists and office assistants (14.7%), or technical and mechanics assistants (15.2%) in industry, crafts and engineering. Women who are trained in personal services in the hotel and restaurant business, as grand-household administrators, or in general service, all of whom have an education at the two-year secondary level, have even higher childlessness (21.5%

to 22.4%) than physicians (15.9%), high-school teachers (17.3%) and medical doctors with a research degree (18.9%) do. They equal the level of childlessness among women with a higher-tertiary degree in the social sciences (22.1%), journalism (22.2%), business administration (21.3%), pharmacy (20.9%), psychology (20.7%), and the natural or technical sciences (20.2%).

In general, we find that women educated for jobs in teaching and health care are in a class of their own, with much lower permanent childlessness than in any other major grouping at each educational level (rate of childlessness among all women with an education in health care: 10.8%, in teaching: 12.5%; average among all women: 15.7%).

Women educated as librarians, artists, humanists, and theologians have much higher childlessness (27.3%) than any other group. In this connection, humanists are women who have a university education in the liberal arts, but who have not acquired the additional qualifications to be a high-school teacher (namely mostly training in didactics). Women with a corresponding background and teaching qualifications are assigned to the group educated to be high-school teachers and have significantly lower childlessness (humanists: 30.4%; high-school teachers: 17.3%). Women who received a (lower or higher) tertiary degree in theology also remain childless quite often (27 to 31% childless). Our companion study on ultimate fertility (Hoem, Neyer, and Andersson 2006) reveals that among women with an education in theology, there seems to be a bifurcation between women who remain childless and women who have a comparatively large number of children.

Women with an education in administration, business, law, and the social sciences have on average a similar rate of childlessness (16.9%) as women with an education in industry, crafts, engineering, and the natural and technical sciences do (16.5%). But there are more sub-categories of educational fields in administration, business, law, and social science in which women show higher rates of childlessness (20% and above) than in industry, crafts, engineering, and the natural and technical sciences.

The pattern of childlessness by educational fields shows that the educational level is not sufficient to make inferences about the relationship between education and fertility levels. It may even lead to wrong assumptions about education and childless-

ness. The educational field is a much better indicator of permanent childlessness than the educational level. Nevertheless, the pattern of childlessness by educational fields does not alone provide a straightforward answer to the question how education and fertility are interrelated. Individual factors and institutional factors seem to intertwine in bringing about the pattern of childlessness that we observe. We will return to this issue in more detail when we discuss our findings below.

We highlight some of these features further in the following subsections.

4.2. Childlessness and mean age at completion of education. One may perhaps expect higher childlessness among groups that complete their education relatively late, and to some degree Figure 2 bears this out. However, as with the association between educational level and childlessness, this applies primarily to educations in the same field. Even within a field of education we do not always find that longer education leads to higher childlessness. This may be partly attributed to the character and flexibility of the Swedish educational system. Several of our educational categories are second educations or educational extensions, so there is no clear causal relation between recorded age at completion and entry into motherhood. One of the most interesting features of Figure 2 is what it tells us about the timing of educational completion in Sweden. We notice that on average women take their doctorates at a relatively advanced age (namely in their mid-thirties), and that master's degrees in psychology and social science are completed around age 33 on the average. We are not sure why the latter groups take so much longer than other academics to complete their master-level studies, but we suspect that for many students, psychology may be a continued education after some previous line of study or that many students of psychology pursue some clinical or therapeutic training, which may prolong their studies. Women educated as teachers for children with special needs are in a similar category, in that such an education typically is taken as a later specialization by people who already are qualified teachers. (The education as a "special-education teacher" was completed at age 34.5 on average in our cohort.) Similarly, education as a deaconess ("brief religious education") often succeeds some other previous training. Some educations require previous certificates or degrees, the way all higher university degrees do. To become accepted into a program for midwifery, for example, a woman needs to be an accredited nurse. Such requirements explain why midwife certificates are attained as late as at age 30 on average.

If we pay special attention to educational lines in which the mean age at first childbirth is lower than the mean age at which education is completed, we find that most of them are in health, care, and teaching (see Table A2). At this stage of our analysis we are not able to determine whether this is because (a) these educational lines are organized in a way that makes it easier for women to combine studies with childrearing,<sup>19</sup> (b) women who had a different education before they became mothers subsequently took an education in one of these fields, or (c) the education we see is an update or a further qualification in an educational line which these women had already completed before the birth of their first child. However, we note that almost all educational lines in which the mean age at first birth is lower than the mean age at completion of education lead to employment in the public sector. This may be due to the better possibilities for combining motherhood and work in the public sector, but it may also result if public-sector employees get re-trained in educational institutions (rather than on the job) and thus more easily get discovered by the recording system.<sup>20</sup>

In general, we find that if the mean age at which education is completed exceeds age 30, women tend to have their first child before they finish their education; in fact the mean age at entry into motherhood lies around age thirty even for those who take their final exams on average in their mid-thirties. This might explain why childlessness among women with a long education does not deviate markedly from our general pattern (namely, the pattern that the educational field is important with regard to childlessness). It further calls into question any assumption that a long education in itself might lead to increased involuntary childlessness because women postpone childbearing until they have completed their education; they do not. The Swedish case rather shows that if an educational system allows women to continue their education after they have become mothers, women may use such an option.

---

<sup>19</sup> We thank the anonymous reviewer who suggested this interpretation to us.

<sup>20</sup> Note that any comparison between means could lead to biased results regarding the patterns of educational and childbearing histories. To disentangle the interrelationship between educational histories, childbearing histories, and childlessness across educational fields would involve different methods and more extensive analyses than what we can present at this stage.

[Figure 2 about here]

4.3. Outliers. Some educational groups appear to be essentially different from others in terms of childlessness. Here are some that have struck us.

4.3.1. *Outliers 1: Groups with more than a quarter childless.* Women educated in arts and humanities and for religious occupations have unusually high fractions permanently childless. As we shall see below, women with a religious education do not have particularly high percentages never married, quite on the contrary.<sup>21</sup> We suppose that some particular selection process is involved. So much childlessness is particularly remarkable for women with a brief religious education, who often become deaconesses. Despite the fact that a high fraction of women educated in theology work in the field in which they are trained (Ahola 1999, 26), about a third go into other occupations. Deaconesses often go to occupations in the care and charity sector or into youth work. Other women with an education that lead to similar occupations (such as nurses or educated youth workers) have low fractions childless. We shall return to these educational groups when we study their ultimate number of children in our companion paper (Hoem, Neyer, and Andersson 2006).

One might speculate that an education which does not lead to a regular and rather predetermined occupation might entail a more uncertain life, something that could make it less compatible with childbearing than other types of education. This may be true for our artists and (non-teaching) humanists, whose education often leads to free-lance work, but this line of reasoning hardly fits librarians, who also have unusually high fractions childless despite the fact that their education is a direct preparation for their normal occupation. On the other hand, artists, humanists, deaconesses, and librarians most often have a relatively low mean annual income compared to other women on the same educational level, and this may be a disincentive to have a child.<sup>22</sup> Weak earnings alone do not seem to work toward increased childlessness, however, as we see if we bring other educational groups into the picture. Women with an

---

<sup>21</sup> We would expect theologians and others with a religious education to confine even their first childbearing to marriage, which is hardly the case for most other educational groups in Sweden.

<sup>22</sup> We do not display our income data in detail here. For references showing how low earnings are associated with reduced entry into motherhood among Swedish women, see Hoem 2000, Andersson 2000.

education as cleaners, service workers, or beauticians, for example, have mean annual incomes that are lower than or equal to those of artists, humanists, or librarians, but these less highly educated groups do not have anywhere as high fractions childless. We assume that a perception of relative deprivation may play a role. Librarians (say) may possibly compare their own incomes with other women with a tertiary education rather than with less highly educated service personnel, and may adjust their childbearing accordingly, but we suspect that there are some further explanations, such as special preferences or social norms among librarians, that go beyond what we can see in our data (or otherwise in the empirical literature).

4.3.2. *Outliers 2: Groups that never marry.* In Sweden, marriage formation is only partially related to childbearing. In 1980, when our cohort was between 21 and 25 years old, almost 40% of all births were out of wedlock; the rate increased to almost 50% by 1985, and it had gone beyond 50% by 1995 (Council of Europe 1999, 67). Nevertheless, marriage is an indicator of a heterosexual relationship and thus a marker of “being at risk” of pregnancy. We have therefore plotted the per cent childless in our educational groups against the per cent never married in Figure 3. The stippled segmenting line indicates where the two percentages add up to 45, and we have drawn it because it seems to largely separate the educational groups into recognizable clusters, much as the famous Hajnal line separated the countries in Europe by dominant family types (Hajnal 1965). Evidently, groups educated for teaching or health provision have both low percentages never married and low percentages childless. Education for administrative, economic, and social-science occupations scores notably higher on both dimensions. The religiously educated form a group for themselves, with low percentages never married (around 20%) and high percentages childless (almost 30%), manifesting another aspect of the bifurcation that we mentioned earlier. The artists, humanists, and librarians, but also women educated for the hotel- and restaurant business, end up with high percentages on both counts; note how they spread around the forty-percent-point never married. There may be two explanations for these relationships: First, women with a preference for a life-style without marriage and children might opt for particular educations, such as the arts and humanistic lines (see also Andersson et al., 2004, Table 2; and Jensen 1973, 275). Second (and conversely), women might adjust to the norms in their professional group (such as being single as a life-style) or to circumstances of profession that may work

against marriage and/or childbearing (such as long working hours or night-work) (see also Cooney and Uhlenberg 1989; Vesselier 1976; 1989; Bressler and Kephart 1954; Cookingham 1984, Preston 1994; Gjerberg 2002).

[Figure 3 about here]

4.3.3. *Non-outliers: Women with research degrees.* Swedish women with research degrees (licentiates or doctorates) end up completing their degrees in their mid-thirties on average. They tend to have fractions childless on the high side for their line of education, but otherwise do not appear systematically different from other women. This is all the more remarkable as both economic and culture-based theories would lead us to expect particularly high fractions childless among these most highly educated women. In our eyes, this finding (and the corresponding finding about their ultimate number of children in the companion paper) throws considerable doubt on both types of theory.

## 5. Reflections on our main findings

After the foregoing description of the patterns that have struck us most prominently in our findings, we now confront our reflections in the previous sections with our empirical findings. At this stage of our work we are not in a position to test all hypotheses empirically; nevertheless we want to review them in the light of our results. This should provide some indications as to where future research should be directed, theoretically and empirically.

5.1. The gender structure of the educational system. The low rate of childlessness among women with an education in health, care, and teaching<sup>23</sup> gives some support to the hypothesis that a high share of women in an educational line leads to lower childlessness. In Sweden, as in many other countries, women make up the vast majority of all upper-secondary graduates in health care and in child recreation, and of the higher-education students and graduates in health-related educations (about 85-90% in each group, medical science excepted) as well as in teaching (75-80%).<sup>24</sup> Women

---

<sup>23</sup> Music and arts teachers are excepted; we count these groups together with artists.

<sup>24</sup> These statistics refer to the period from the mid-1970s to the end of the 1980s. They thus roughly represent the time when most of the women in our cohort took their education. Such rates have not

dominate the study lines for child- and youth pedagogies (pre-school and after-school teaching), education for children with special needs, and also home economics (more than 90% of all students and graduates in each case; Statistics Sweden 1997, 375f.). All of these groups have rather low rates of childlessness. We find a similar association between a clear female dominance and low rates of ultimate childlessness in several other educational fields, such as education for work with textiles and clothes production (about 95% women) or pharmacy receptionists (91% women).

The association is less convincing in fields of education with a more mixed gender distribution, that is where women make up about 40% to 66% of the students or graduates, or in fields of education where women are a minority (below 40% of graduates). For example, women constitute about 66% of the graduates from the humanities; in law and the social sciences they comprise 55%; and in the fine arts and medical sciences about 50-52%. Contrary to what one would perhaps expect from the gender-dominance argument, childlessness in these groups is highest among humanists and lowest among physicians. Moreover, there is a big discrepancy in the level of childlessness between physicians and women with a degree in the fine arts, despite the fact that both groups study in environments with similar gender distributions. In our eyes, selectivity mechanisms are at work, combined with differences in working conditions for the various groups.

Similarly, there are about as many women as men among the upper-secondary graduates in food processing and in the hotel and restaurant business, but their rates of childlessness differ considerably (food processing: 14.0%, hotel and restaurant workers: 22.4%). Women with an education in technology and engineering, where graduates are less than 25% female, have almost as much childlessness as women with an education in business and administration, where somewhere between half and two-thirds of the graduates are women.

Thus, on the whole, a higher share of women in an educational field does not lead systematically to lower childlessness, unless women outnumber men at a ratio above three-to-one. The level of childlessness among women who took an education in a field with a mixed gender structure (social science, humanities, arts, personal services, business and administration, law) varies markedly. For women with a tertiary

---

changed much since. Sources: Stanfors 2003, p. 78, Table 4.3; and pp. 256-257, Table A8.20, our calculations. See also Statistics Sweden 1997, pp. 366-370 and 375f., Table 426.

education we even find that on average women with a degree in a male-dominated field (where there is less than 25% women, as in some natural sciences and in technology) may display lower childlessness than women in a field with a more gender-equal student body (as in the humanities, arts, law, pharmacy). Evidently, fertility outcomes are not a simple matter of “the higher the share of women, the lower the childlessness”; an explanation of childlessness must be multidimensional.

5.2. Education and the labor market. We can group educations into five broad clusters according to the labor-market and employment situations they most often lead to. The levels of childlessness only vaguely reflect the expectations we voiced in Section 2.2.

*5.2.1. Education leading to a reliable employment career in the public sector.* First, women educated in health, care, and teaching have chosen educational lines with a rather calculable future employment career, and they also have the lowest level of childlessness, as we have noted several times already. Most women educated in one of these fields are employed in the area in which they are trained in; they work in highly feminized occupations and in the public sector (Melkas and Anker 1998, 14; Statistics Sweden 1997, 173f; Ahola 1999; Smyth 2003). As we pointed out earlier, the public sector offers greater employment security, stable income prospect, more flexible work-time opportunities, and higher parental-leave benefits<sup>25</sup> than the private sector normally does, and the public sector is therefore the more conducive to childbearing and childrearing. However, as the higher level of childlessness among women who also work in the public sector, but are educated to be music and arts teachers, librarians, or pharmacy employees<sup>26</sup> shows, public-sector employment or female domination do not in themselves lead to lower childlessness.

*5.2.2 Highly feminized occupations in the private sector.* Our second cluster comprises educational lines that lead to highly feminized occupations in the private sector. Such areas comprise a wide range of educational fields, among them food processing, textile work, beauticians and hairdressers, and service in hotel and restau-

---

<sup>25</sup> Public sector employers usually grant additions to the parental-leave benefit so that public-sector employees receive essentially full income compensation during parental leave. By law, the parental-leave benefit in Sweden currently amounts to 80% of a person’s previous income (up to a certain high level).

<sup>26</sup> Pharmacies in Sweden are state owned.

rant businesses. The spectrum of educational-occupational dissimilarity (that is the range of jobs that the women hold that do not match what they were trained in) is somewhat wider than in the area of health, care, and teaching. In declining industrial fields, such as textile work, the job-mismatch may be even larger (Ahola 1999). But depreciation of education during employment breaks is often lower than in the health professions. The rate of childlessness in these areas seems to depend on the working conditions, including how precarious job contracts tend to be. Not surprisingly, women who chose an education that leads to occupations with time-demanding working conditions (long or odd working hours) and high employment mobility, such as the hotel and restaurant business, have higher levels of childlessness than other women.

*5.2.3. Gender-mixed educational lines with little occupation-specificity.* Our third educational cluster consists of gender-mixed educational lines that are not really directed to any specific occupation. This group includes women who leave the educational system after primary school or after a general upper-secondary education without a real vocational component. It also comprises education in the humanities, fine arts, or general social science. Women with such a background face greater difficulties than others in their transition to the labor market (Korpi, de Graaf, Hendrickx, and Layte 2003) and they end up in very diverse jobs, such as in clerical work at various levels, in libraries, schools, general administration, and so on (Ahola 1999, 27f.). Childlessness is moderate to high among these women.

*5.2.4. Gender-mixed educational lines with high occupation-specificity.* By contrast, our fourth cluster encompasses gender-mixed educational lines that offer an occupation-specific education and qualify for jobs with varying employment prospects and varying returns, such as education in business and administration, journalism, or law. In these areas childlessness is generally higher than average, just as in the previous group. The degree of occupation-specificity must matter less than other aspects of education.

*5.2.5. Male-dominated lines of education.* Our fifth and final cluster covers male-dominated lines of education; they mostly lead to private-sector employment. This mainly comprises education in technology, engineering, and the natural sciences. Women with an education in these fields face a longer job-search process after education; they are less likely to obtain a first job with employment security (in their re-

spective field) and their possibilities to maintain employment is lower than in other fields of education (Smyth 2003, 66f.; he argues that there is a second segregation at the level of occupations). Nevertheless, these women surprisingly have low childlessness.<sup>27</sup>

5.3. Selection and adaptation, preferences and social norms: The above discussion of the facts shows that, obviously, the fraction permanently childless in an educational group must be the outcome of many processes that function in interaction with each other. On the individual level, there seems to be a process of selection of women into fields of education, steered both by individual abilities, interests, preferences (Hakim 2000), and by social and normative influences. Social background, the structure of the educational system, and norms and conventions concerning what kind of education and what ensuing occupations are suitable for a woman each play a role in this process.<sup>28</sup> The type and level of education a woman successively attains are determinants of her employment, her income security, her career opportunities, and her work environment, and then also of her reproductive behavior. Since we may assume that (at least to some extent) there is a purposive element in most people's decisions, these considerations presumably work both ways, so a woman's evolving perception about the kind of life an education may lead to and the social and economic conditions that her education provides, is an active element in her decision process. We may therefore expect a dynamic interaction between a woman's educational path, her childbearing plans and preferences, and her actual childbearing.

---

<sup>27</sup> Note that women with a mechanic's education have one of the highest fractions never-married, nevertheless they have very low childlessness.

<sup>28</sup> Many studies (e.g.: Jonsson 1999; Breen and Jonsson 2000; Dryler 1998 ) show how important a girl's social environment is in her "choice" of field of education. Jonsson (1999, 400) shows that although Swedish pupils' perception of their "comparative advantage" (that is, of their talents and achievements in relation to others) is important for the selection of the line of education (at the secondary level), it does not explain the substantial sex-segregation in the choice of educational programs. The classroom composition and family background constitute a major factor in the choice of subject lines. Our study suggests that considerations about future professional and family life may also have an impact on the choice of the field of education.

In principle, educational opportunities may play a further role, in that a free choice of education may not be available to all women at all times, though the latter issue should perhaps not be so important in advanced industrialized countries in recent decades.

## 6. Education and fertility – some implications for future research

The results of our study have several implications for demographic research. Clearly, better than the mere level of education, the field of education can additionally serve as an indicator of a woman's potential reproductive behavior. Therefore, one conclusion is obvious: In studies of the impact of education on fertility, the representation of educational attainment needs to reflect much more than just the level attained. Adding educational orientation will at least give us a proxy for underlying features connected to education that have an influence on entry into motherhood. Undoubtedly we also need to identify which underlying features associated with education influence fertility behavior, and how. This requires paying attention to the context in which education is provided and thus considering the institutional aspects of education, that is, the structure and organization of education. Moreover, we need to take into account that for many fields of education the labor-market sector in which a woman will work is basically predetermined (although there may be cross-country variation; see also: Hall and Soskice 2001; Estévez-Abe et al 2001; Estévez-Abe 2005; Charles 2005). It seems that for some groups of women the choice of the educational line may be influenced by considerations regarding the potential compatibility of employment and childbearing.<sup>29</sup> We therefore should include institutional aspects of labor markets that reflect the different conditions under which women with different educations work. Whether one can get data on such features or not, they are likely to have consequences for the childbearing patterns that the statistician can observe, and they must be taken into account when observed patterns are interpreted. On the whole, the results of our study suggest that the choice of education does not only mirror a woman's interests, her preferences, her talents, her background, or her professional and economic aspirations, but it also reflects her considerations regarding her potential childbearing plans, however vague such plans may be at the time in life when the decisions about the line of education are made. As a consequence, education cannot be merely viewed as an economic or human-capital indicator, but its impact on fertility needs to be analyzed within an institutional framework that considers the relationship between education, labor market, state, and family. Our analysis pinpoints where one should start to look, but it is evident that we

---

<sup>29</sup> This would partly explain the persistence of gender segregation in educational systems, in particular in countries where specific fields of education lead to employment in sectors with better opportunities to combine childbearing and employment.

are only beginning to discern some of the reasons why groups of women remain permanently childless.

### **Acknowledgements**

The project from which this report is a product, builds on an idea by Britta Hoem to study the link between educational orientation and fertility. She published some of her results (Hoem, 1994) but left most of them unpublished except in an internal report (Hoem and Hoem, 1995). We have benefited from comments to presentations made in Lund, Sweden (11 November 2002), in Rostock, Germany (31 January 2003), and in Münster, Germany (9 October 2003). We are grateful to Statistics Sweden for making the data available to us and for explaining many details about the Swedish educational register.

Jonathan MacGill cleaned the data for us and did the programming to produce the tables on which we have based our analysis. We are also grateful to Kirsten Bohne, Esther Geisler, Anne Hornung, Silvia Leek, Dorothea Rieck, and Anke Schwarz for research assistance. We also thank the anonymous reviewers for many useful comments and suggestions.

## Appendix 1: Data

A1.1. The register data. We have access to individual-level data for all female members of the cohorts born since 1945 and domiciled in Sweden at any time since the census of 1960. Our data have been extracted from the Swedish educational register through the end of 1998 and combined with information for the same individuals from the (Swedish) central population register through 2002.<sup>30</sup>

The central Swedish population register contains all demographic events recorded for the women we study, so long as the events occurred in Sweden. Births that occurred abroad are also recorded if the woman and her child(ren) subsequently entered Sweden. We know the women's own birthdates, all dates on which they have a recorded birth, marriage, divorce, or in- or out-migration across the country's borders, and any date of death. All dates are given to the accuracy of the day. For more details, see e.g. Section 2.1 in Hoem (1997).

In its current form, the educational register<sup>31</sup> is based on information originating from the population censuses of 1985 and 1990, and from annual reports on course completion from the entire educational system in the country. For women who immigrated from abroad, Statistics Sweden has sought to fill lacunas through large-scale mail inquiries, annually in recent years. In principle, the register should cover education completed in Sweden back through 1970 and beyond. For each individual, each entry contains a code for the education completed and it should also contain calendar year of completion. For the early years, the register covers mostly academic courses, but the ambition is to include all types of education. There has been great improvement in coverage and accuracy over the life of the register. Nevertheless, considerable problems remain with duplicate records and, particularly, with missing calendar years at attainment. Table A1 gives an overview of the quality of the records available for women born in Sweden in 1945 through 1964. By a process of elimina-

---

<sup>30</sup> We got an extension by four extra years from the population register as part of a standing data order that does not cover the educational register. We also have access to data (stemming from Swedish tax registers) on annual earnings and public transfers for our study objects during 1980-98. We have not really used the income data in the present study but hope to do so in a future continuation.

<sup>31</sup> For more information, see Odelholm (1998). Åke Nilsson (personal communication) has given us an update.

tion based on the following considerations, we have decided to concentrate our current presentation on the cohort of women born in Sweden in 1955-59.

-- We are concerned with permanent childlessness in this paper, so we have wanted to study women most of whom have finished childbearing. This makes the youngest cohort in Table A1 somewhat less useful than the other cohorts.

-- The number of missing calendar years of educational attainment strikes us as a bit too high in the records of the cohort born in 1945-49. The cohort of 1950-54 may be a borderline case. Both cohorts, however, entered their education before the educational reform of 1962 and the reform of the higher education of 1977. These reforms introduced the comprehensive school system and the main structure of tertiary education which are still in place in Sweden today. We have wanted a study whose results allow us to make some inferences about the current situation as well. Nevertheless, to test the validity of our results, we have handled both the cohort of 1950-54 and the cohort of 1960-64 in the same manner as that from 1955-59, and the results (not reported here) are largely the same as those that we do report.

-- We have not wanted to venture into the more problematic records for female immigrants in the register and have limited our study to women born in Sweden.

**Table A1. Numbers of records and their completeness in the Swedish educational register as of the end of 1998. Women born in Sweden**

Year of Birth	Age at end of 1998 <sup>a</sup>	Age at end of 2002 <sup>b</sup>	Total persons <sup>c</sup>	Per cent with complete records <sup>d</sup>	Per cent with partially complete records <sup>e</sup>	Per cent with no ed years recorded <sup>f</sup>
1945-49	49-53	53-57	299,675	33	10	53
1950-54	44-48	48-52	256,287	45	12	42
1955-59	39-43	43-47	249,607	63	10	25
1960-64	34-38	38-42	258,657	71	10	18

NOTES

<sup>a</sup> Time of extraction of educational data

<sup>b</sup> Time of extraction of demographic data

<sup>c</sup> Swedish-born women only

<sup>d</sup> Per cent persons where all educational records show year of attainment

<sup>e</sup> Per cent persons where some but not all educational records show year of attainment

<sup>f</sup> Per cent persons with educational records but none with year of attainment

A1.2. Coding of educational attainment. In the Swedish statistical system, any recorded item of educational attainment is given a five-digit code (Statistics Sweden, 1996; with subsequent minor revisions). The first digit represents the general orientation of the education, largely as given in the legend to Figure 1. The second digit represents educational level, essentially as given on the  $x$ -axis of Figure 1 and as described further in connection with that diagram. The three final digits represent further sub-specification. For instance, the code 26731 is used for individuals educated in teaching (the digit 2) in a study-program that is supposed to take three years or longer and lead to a university-level degree (the digit 6) in the fields of mathematics (7), physics (3), and geography (1). In everyday terms 26731 indicates that this person has been educated as a high-school teacher in the mentioned subjects. The code 26732 is for corresponding teachers in mathematics, physics, and chemistry.

Potentially there are about 100,000 codes in this system. In practice, we have found about 2900 codes used for women born in Sweden. This is much too many categories for the kind of representation we use, so we have grouped them into some sixty meaningful types of education according to their characteristics. The resulting grouping is most easily evident in Table A2.

For our graphical representation, we have adapted the coding of the statistical system as follows.

-- The statistical system groups education for pharmaceutical work (pharmacy technicians, pharmacy receptionists, pharmacists, and laboratory assistants) under the health professions. We have reclassified them so they are together with women educated for the natural sciences because we feel that this better reflects the nature of their work and their workplace situation; women in pharmacy work are not concerned with clients as patients the way nurses and physicians are.

-- In Figure 1 we have used the same symbol to represent women educated for teaching and women educated for the health professions. We believe that their common orientation toward pupils and patients is more important than the fact that they come under different headings in the statistical system.

-- We have used one symbol to represent women educated for postal services (mail carriers, post-office employees) and for personal service (homemaking, cleaning, food processing, work in hotels and restaurants, beauticians, and so on). Women

educated for police work have also been marked by the same symbol. This is just to simplify the diagram.

-- There are additional codes for education aimed at jobs in agriculture, and two of the categories (concerning women trained as farm workers) are listed in Table A2. Their childlessness fractions largely overlap with groups of women educated at similar levels for other kinds of non-caring and non-teaching jobs,<sup>32</sup> and we have not included them in Figure 1 so as not to mess up the diagram needlessly with this small group.

-- With the combinations we have used, most of our educational groups have a reasonable size, but we have had to combine women with a doctorate in the humanities with women with a doctorate in the administrative and social sciences to get anything like a group that is big enough to avoid domination by random variation.

A1.3. Data cleaning. For our purposes, an ideal set of educational records for an individual would contain a sequence of accurate educational codes, each of which would be paired with a date of course completion that is accurate enough to (i) reflect real course completion and (ii) to avoid most ties, i.e., two or more codes with the same recorded times of completion for an individual.<sup>33</sup> An accuracy of a calendar year is much too coarse for both of these purposes. Individuals can easily have two or more correct educational records in a single year, particularly since the Swedish educational register catches completions down to individual semester-length courses in many cases. Given the active dynamics of the Swedish educational system, an individual can also have a correct record of a lower-level education after a chronologically earlier correct record of a higher-level education. Such “disorder in the life-course” does not allow data-cleaning on the basis of a unidirectional and monotonic concept of the educational life-course.

Since the educational register has been built up successively over time, an additional complication arises when the register manager discovers that a younger and presumably more correct record disagrees with an older record, either in terms of edu-

---

<sup>32</sup> For instance, 20 per cent of female agronomists and veterinarians are childless in our cohort. This fraction is similar to that for other academics educated for jobs outside the teaching and health professions.

<sup>33</sup> Such a tie could actually be possible namely if, for example, someone studies at two lines and finishes them at the same time. Such coincidences are rare and we have disregarded them.

cational code or recorded year of attainment. In the register, therefore, each record has an additional item, namely the year the item was recorded. This has been useful during our considerable cleaning of the educational data.

In our cleaning process, we have removed duplicate records and ties, for simplicity leaving at most one educational record per person per calendar year, covering the status at the end of the year. We have let a newer record supersede an earlier one with which it is inconsistent. And finally, where year of attainment was still missing, we have imputed one by inserting the cohort's average year of attainment for the given educational code, within constraints set by chronologically preceding and following records for the same individual. We computed this average empirically across individuals with the same educational code for which the year was recorded. Cleaning was made iteratively until convergence.

Note that this means that we have not inserted the year of attainment implied by a regular progress through the educational system, as defined normatively by official descriptions of educational lines, because the official description does not correspond even approximately to school realities. (Thus we have not imputed, say, the calendar year in which an individual attains age 19 for the completion of secondary school.) This is also evident from the column called "mean age at completion of education" in Table A2. Those mean ages are regularly much too high as compared to a normative description. Kravdal (2004) has shown that the assumption of a regular progress can be much inferior to empirical imputation.

If we accept the imputed missing years of completion, we can characterize each respondent's educational attainment for any year up through 1998 in our data. This feature has been useful for some experiments to be reported presently.

For the present paper, therefore, we have attempted to get as close as possible to each woman's highest educational attainment by the end of her educational career, and have used that attainment in our analyses, for instance in Figure 1 and Table A2.

In practice, we have settled for her educational attainment by the time of data extraction (*viz.*, at the end of 1998). We have done so both for our main cohort (born in 1955-59 and thus aged 39-43 at that end-date) and in a supplementary analysis of the neighboring cohorts (aged 34-38 and 44-53, respectively, at the end-date). Note that the data for the two immediately older cohorts go to higher ages than the data for

our youngest cohort. To make the cohorts more comparable, we have as an experiment also studied childlessness at the end of the reproductive period according to education completed by age 35 for each cohort. In the cohorts that we can follow to higher ages, there is considerable dynamics in recorded educational attainment after age 35. (See our companion paper for some such features; we do not otherwise report details of this nature.) Nevertheless, the results on permanent childlessness are only different in a minor way from what we record here, even when education is measured at age 35. Such differences as we have found are easily attributable to random variation in the smallest of our educational groups. We get the same type of outcome when we study ultimate fertility in similar experiments made for our companion paper.

Women who have left or entered Sweden before the end of 1998, or for whom we have a death record before that date, represent a complication, which we have handled as follows. Those who left the country before the end of 1998 and for whom we have a subsequent return record, we have used educational status at the end of 1998, just as for the stationary population. For women who left Sweden before the end of 1998 and who did not return by that end-date, we have used their educational attainment at out-migration. For (the few) women who did not survive to the end of 1998, we have used educational attainment as recorded at death.

Out-migration and non-survival cause similar trivial problems for the definition of permanent childlessness. We have handled them as follows:

- For women who left the study population through death, we have used the childbearing records until death.
- For women who left the population by out-migration without returning before the end of the study period, we used the childbearing records until out-migration.
- For women who left the population by out-migration but then returned, the childbearing records were completed on subsequent in-migration, and we have used the complete childbearing records.

A1.4. Method of analysis. Our method of analysis is so straightforward that it does not really need any extensive description, but some comments may still be in order. We have concentrated on the final reproductive-lifetime outcome, and have computed the per cent permanently childless in each educational group, defined according to the highest level of education ultimately attained in our records.

We would have liked to use event-history methods in our analysis as well, but with the current data set, we have not ventured down that road at the present stage. Despite all the strengths of the data from the educational register, there simply is too much uncertainty about the accuracy of the timing information in the educational histories of the cohorts that have completed their childbearing.<sup>34</sup> Our current method has the merit of simplicity and the advantage that the procedure can be repeated for any country that has similar information on childbearing and educational attainment. We only get a pale reflection of the dynamics that constitute our main explanation of the patterns revealed. Nevertheless even this adds a new dimension to our understanding of the connection between education and childbearing.

In statistical terms, our procedure can be interpreted as follows: We are confronted with a two-dimensional outcome, with a childlessness indicator as one variable and final educational attainment (defined in terms of both level and field of education) as another. We study the structure of the distribution of the former variable, conditional on the outcome of the second. We trust that this structure gives us new insights into the underlying dynamics that we are really interested in.

To avoid the impression that we are making an error that we ourselves have often warned against, we want to underline that our procedure does not amount to anticipatory analysis (Kravdal 2004). We are conditioning on the final outcome of one process (educational attainment), but we do not study the timing of entry into motherhood in parts of the lifecycle before the time of that final educational outcome. Conditioning on the future of one dimension in a study of the dynamics of the other can produce well-known biases in findings about the latter, but we only study the final outcome of the childbearing process and not its dynamics, so those biases should not arise.

Our most important analytical tool at this stage of the present project is diagrams of the nature apparent in our figures. Our approach invites a case-by-case investigation of meaningful nominative educational groups. It mimics procedures often used in studies of occupation mortality, where a case-by-case discussion of the mortality in distinct nominative occupations is often used. We feel that we have gained much more insight from this practice than by only using a woman's educational level,

---

<sup>34</sup> A study by Lappegård and Rønsen (2005) suggests that our Norwegian colleagues have more adequate data at their disposal, or else they are more courageous than us.

let alone by representing that level by the number of years of education she is supposed to use to reach that level, as is often done. The nominative groups much more easily inspire substantive explanation and theory formation, reveal open questions, and easily provide counter-examples for theory elements that do not stand up to closer scrutiny.

## Appendix 2
